What is “Signal Conditioning”? 

There are many factors which may prevent a signal produced by one device or circuit from being usable by another device or circuit, requiring some intermediate circuitry to bridge the gap. This kind of “bridging” function is doing what I call “signal conditioning”.

Clipping

Often it's necessary to ensure that a signal does not exceed a certain voltage in order to avoid harming circuitry which follows. For instance, a sensor inside the engine of a car may pick up electrical noise of hundreds of volts occasionally which could destroy a microprocessor. To avoid this, the signal may be clipped so that it never goes above a fixed voltage. This can be done using a Zener diode.

Digital

Sometimes digital signals in a system need to be cleaned up. This can be in order to do one or both of:

- remove noise from the signal
- change the duration of the signal

These two cases will now be discussed.

The purpose of isolation is to remove large DC offsets from a signal. (Of course it could be to add a DC offset instead.) An op-amp can be used to remove small DC offsets, of the same order of voltage as the supply voltage. Sometimes hundreds or thousands of volts must be removed. (For instance, inside a car engine, the ignition system produces sparks of thousands of volts, while the electronics runs on normal logic levels. The spark plug voltages could not be directly sensed by the microprocessor. At least more than once.....)

An analog switch works just like a mechanical switch in allowing an analog signal to flow between two points in a circuit when it is closed, and preventing the flow when it is open. The difference with an analog switch is that the control of the opening and closing of the switch is provided by a digital signal. Like mechanical switches, there are a variety of switch types, such as SPST, SPDT, DPDT, and so on. The resistor $R_{on}$ is to indicate a finite resistance between the input and output when the switch is closed. The value of $R_{on}$ should be in the device specifications.

Basic BJT Operation

The BJT operates as a current amplifier. In the common emitter configuration, controlling the current to the base results in change to the collector current. Since $\beta = \frac{I_c}{I_b} \approx 100 \rightarrow 500$, then a substantial increase in current is possible. A few choices of how to do this in a circuit follow. (NPN transistors will be assumed. It's easy to change to PNP after you understand the principles.)

Darlington Transistors

If a very great current gain is desired, i.e. up to \( \approx 1000 \times \), a Darlington configuration may be used. This has the emitter of one transistor fed directly into the base of another, with the collectors in common. In this way the two \( \beta \) values get multiplied, so a much greater gain is possible. Darlington transistors are devices which are connected this way internally, so they look like an ordinary transistor from the outside.

Grounded Load
Grounded Load

In this configuration, the load, shown as a resistance $R_l$, is placed between the emitter of the transistor and ground. It is often useful to have one end of the load grounded. For a transistor to be “on”, the base–emitter junction must be forward biased so

$$V_{be} \geq 0.7V$$

This means that the base of the transistor must be able to go above the highest load voltage desired.
Floating Load
Floating Load

If the base voltage cannot easily be raised above the desired load voltage, it is possible to place the load between the collector of the transistor and the supply voltage, and then ground the emitter of the transistor.
